

Uneven horizon or several words* about the superfluid ${}^4\text{He}$ theory

Maksim D. Tomchenko $^\diamond$

Department of Astrophysics and Elementary Particle Physics,
Bogoliubov Institute for Theoretical Physics, Kiev 03143, Ukraine.

The state of the superfluid He-II theory is briefly surveyed — some aspects of its history, achievements, and unsolved problems.

Key Words: Superfluid ${}^4\text{He}$; Condensate; Quasiparticle Spectrum.

1 Introduction

In the first years after the discovery of superfluid He-4, the property of superfluidity attracted attention not only due to its uncommonness but also to the hope of some physicists for its connection with the basically new, still undiscovered laws of the microworld [1]. After seven decades from the discovery of the superfluidity (P. Kapitsa [2], J. Allen, A. Misener [3]) and a century from the time when He-4 was fluidized (H. Kamerlingh-Onnes [4]), it becomes clear that superfluid helium justified hopes for the manifestation of a number of unusual properties, but no “new physics” has arisen because of helium.

In what follows, I will characterize briefly the state of the theory of superfluid He-4 (He-II) and mark the unsolved questions. In this case, I do not pretend to the completeness of analysis or references and do not try to avoid the own sympathies for some questions. The other reviews on the theory of superfluidity He-II are, for example, [5]–[7], and a short one is presented in [8].

2 History

A phenomenological theory of superfluidity was constructed by L. Landau [9, 10] in the 1940s. His key idea consisted in that He-II is a quantum fluid, in which motions can be only collective, i.e., in the form of quasiparticles. L. Landau formulated a criterion, according to which a quantum fluid is superfluid (SF), if its spectrum of quasiparticles (the curve of the energy ϵ of quasiparticles as a function of momentum p) does not touch with the momentum axis, i.e., it has no points with $\epsilon/p \rightarrow 0$. L. Landau proposed to describe a gas of quasiparticles as the “normal component” of the fluid, and the “rest fluid” represents the SF-component. This yields the two-fluid hydrodynamics of He-II which allowed one to explain a number of properties of helium [11, 12]. But this theory is phenomenological and does not clarify the structure of quasiparticles. Therefore, the analysis within the two-fluid hydrodynamics can lead to the erroneous look at phenomena in some cases.

A microscopic theory of He-II was started in a number of works. F. London assumed [13] that the superfluidity of helium can be related to the presence of a condensate in it. On the basis of this idea, L. Tisza [14] constructed a two-fluid hydrodynamics of He-II, in which the SF-component coincides with the condensate. The last assumption turned out false; a more correct two-fluid model was developed by L. Landau [9, 10]. A. Bijl [15] proposed an

approximate structure of the wave functions of the ground and first excited states of He-II:

$$\begin{aligned}\Psi_0 &\approx C e^{\lambda\varphi_1+\lambda^2\varphi_2+\dots}, \quad \varphi_1 = -\sum_{j>l} \gamma(r_{jl}) - \sum_j \mu(\mathbf{r}_j), \\ \Psi_{\mathbf{k}} &\approx \Psi_0 \sum_j e^{ikx_j},\end{aligned}\tag{1}$$

λ — the interaction parameter. The microtheory obtained the strongest stimulus due to the works by N. Bogoliubov [16, 17] and R. Feynman [18, 19]. In particular, the field-theoretic (FT) approach [16] allowed one to calculate the spectrum of quasiparticles (phonons) and the relative number of atoms of a condensate (below — “value of a condensate”) for the system of interacting bosons under condition for the interaction strength to be small. The FT-approach involves the operator formalism and relevant methods. Then it was developed in a number of works, in particular, in [20]–[23].

More significant results were obtained within quantum mechanical (QM) approaches allowing one to calculate, in various ways, the full N -particle wave functions (WFs) of He-II such as those of the ground state (Ψ_0), the states with one quasiparticle $\Psi_{\mathbf{k}} = \psi_{\mathbf{k}} \Psi_0$, and the states with many quasiparticles

$$\Psi(\mathbf{r}_1, \dots, \mathbf{r}_N) = \prod_{i=1}^n (\psi_{\mathbf{k}_i})^{n_i} \Psi_0.\tag{2}$$

It is worth noting that the interaction of quasiparticles in the structure was not considered (2). The first sequential works in the QM-approach were executed by R. Feynman [18, 19]. By using the variational method, he obtained the approximate formula

$$E(k) \approx \frac{\hbar^2 k^2}{2mS(k)}\tag{3}$$

for the spectrum of quasiparticles (SQ) of He-II, $E(k)$, which indicated, for the first time, that the roton minimum of $E(k)$ is related to a maximum of the structure factor $S(k)$, i.e., to a short-range order in the fluid.

The first works by R. Feynman were followed by the articles by N. Bogoliubov, D. Zubarev [17] and R. Jastrow [24] published simultaneously. In work [15], the logarithm of Ψ_0 was sought in the form of the expansion of (1) in the interaction parameter. It was shown in [17] that such a theory of perturbations is not fully correct. There, it was refined, and a new model of weakly nonideal Bose-gas combining the QM- and FT-approaches was proposed; the zero approximation $\psi_{\mathbf{k}} = \rho_{-\mathbf{k}}$ was deduced, and the SQ of a Bose-gas,

$$E(k) = \sqrt{\left(\frac{\hbar^2 k^2}{2m}\right)^2 + 2n\nu(k)\frac{\hbar^2 k^2}{2m}}, \quad \nu(k) = \int V(r) e^{-i\mathbf{k}\mathbf{r}} d\mathbf{r},\tag{4}$$

coinciding with (3) at the weak interaction was found. Work [17] induced the development of QM-approaches with the use of collective variables $\rho_{\mathbf{k}} = \frac{1}{\sqrt{N}} \sum_{j=1}^N e^{-i\mathbf{k}\mathbf{r}_j}$ ($\mathbf{r}_j$ — coordinates of helium atoms). However, that work did not else show that the logarithm of Ψ_0 can be most explicitly expanded in the correlation series

$$\ln \Psi_0 = \sum_{j<k} u_2(\mathbf{r}_j - \mathbf{r}_k) + \sum_{j<k<l} u_3(\mathbf{r}_j - \mathbf{r}_k, \mathbf{r}_l - \mathbf{r}_k, \mathbf{r}_j - \mathbf{r}_l) + \dots\tag{5}$$

Similar, but yet not fully correct, structure of WF Ψ_0 was proposed in [24], where u_3 was sought in reduced form $u_3(\mathbf{r}_j, \mathbf{r}_k, \mathbf{r}_l) \sim f(r_{kj})f(r_{jl})f(r_{kl})$ and was not clearly indicated, that

just the logarithm of Ψ_0 should be expanded (it was shown in [15, 17]). R. Jastrow did not know, probably, work [15], where structure (5) was almost deduced. The proper structure (5) was proposed independently and almost simultaneously by E. Feenberg [25, 26], C.-W. Woo [27], T. Regge [28], and I. Vakarchuk, I. Yukhnovskii [29]. Moreover, works [29] present a method of calculation of the fine structure of Ψ_0 and $\Psi_{\mathbf{k}}$ [see formulas (6) and (7) below].

From the historical viewpoint, it is interesting to note that work [16] was reported by N. Bogoliubov at the Landau's seminar, where it was criticized. One of the results of that work was SQ (4) which has a minimum in the region of finite momenta at a certain potential $V(r)$. L. Landau noticed, without any doubts, this fact and submitted his famous work [10] for publication already in a week, where he predicted correctly the spectrum of quasiparticles of He-II measured later on (Fig. 1). However, the work by Landau contained no mention about the Bogoliubov's model ...

Fig. 1: Experimental spectrum of quasiparticles of He-II.

I also note that the Soviet researchers in the USSR met difficulties as for the publication on the western journals published in English. The direct publications in the West were forbidden by the internal censorship, and they were possible mainly with delay through several journals published in Moscow and translated abroad. However, due to the hostility between the Bogoliubov's and Landau's schools, the representatives of the former had no way to the world scientific literature, since this way passed through Moscow journals. For this reason, the works by I. Yukhnovskii and I. Vakarchuk [29]–[31], in which one of the best modern QM-methods (see below) on the basis of work [17] was developed, remained little known. One would expect that the period of totalitarian regimes terminates, all journals will be open for the authors from any country, and science will be aimed at only constructive purposes.

3 Modern quantum-mechanical models of the microstructure of He-II

The development of ideas advanced by London, Bijl, and mostly by Feynman and Bogoliubov, has led to the appearance of a lot of articles, from which four QM-methods should be selected: the methods of collective variables (CV) [28]–[32, 8], “correlated basis functions” (CBF) [33]–[36], “hypernetted chains” (HNC) [37]–[40], and “shadow wave functions” (SWF) [41]–[44].

The method of CV was developed in [30]. There, the WFs of the ground and first excited states, Ψ_0 and $\psi_{\mathbf{k}}$, are sought in the representation of the collective variables $\rho_{\mathbf{k}}$ in the form of infinite series

$$\Psi_0 = \frac{e^{S_0}}{\sqrt{Q_n}}, \quad S_0 = \sum_{l \geq 2} \frac{N^{1-l/2}}{l!} \sum_{\mathbf{k}_1, \dots, \mathbf{k}_l \neq 0} \delta(\mathbf{k}_1 + \dots + \mathbf{k}_l) a_l(\mathbf{k}_1, \dots, \mathbf{k}_l) \rho_{\mathbf{k}_1} \dots \rho_{\mathbf{k}_l}, \quad (6)$$

$$\psi_{\mathbf{k}} = \rho_{-\mathbf{k}} + \sum_{\substack{\mathbf{k}_1 \neq \mathbf{k} \\ \mathbf{k}_1 \neq 0}} \frac{b_2(\mathbf{k}, \mathbf{k}_1)}{2! \sqrt{N}} \rho_{\mathbf{k}_1 - \mathbf{k}} \rho_{-\mathbf{k}_1} + \sum_{\substack{\mathbf{k}_1 + \mathbf{k}_2 \neq \mathbf{k} \\ \mathbf{k}_1, \mathbf{k}_2 \neq 0}} \frac{b_3(\mathbf{k}, \mathbf{k}_1, \mathbf{k}_2)}{3! N} \rho_{\mathbf{k}_1 + \mathbf{k}_2 - \mathbf{k}} \rho_{-\mathbf{k}_1} \rho_{-\mathbf{k}_2} + \dots, \quad (7)$$

where the l -th term describes the l -particle correlations; δ — Kronecker delta, N — the total number of helium atoms. By performing the direct substitution of Ψ_0 (6) and $\psi_{\mathbf{k}}$ (7) to the exact N -particle Schrödinger equation, we can verify that Ψ_0 and $\psi_{\mathbf{k}}$ satisfy it and can find an infinite chain of linked equations for the functions a_l and b_l . These equations are exact, but the whole chain cannot be solved analytically or numerically. Therefore, it is truncated, and only the first terms describing two-, three-, and sometimes four-particle correlations are retained. Such equations can be already solved numerically [8, 32, 45]. The method allows one to reproduce the experimental SQ of He-II with good accuracy, as well as the energy of the ground state (E_0) and the values of condensates, but with worse accuracy. The analysis can be carried out without fitting parameters (FPs), by using the structure factor $S(k)$, or with FPs, by using the pairwise potential $V(r)$.

In the CBF method, the solution for $\psi_{\mathbf{k}}$ is also sought in the form (7), and the functions b_l and $E(k)$ are determined by the Brillouin–Wigner theory of perturbations with regard for only, as usual, two first terms in (7). The method allows one also to calculate the SQ with good accuracy. The best results are obtained in [35] without FPs and in [36] with several FPs. In [33]–[35], the WF Ψ_0 was not calculated. These works used many-particle distribution functions under certain assumptions and did not apply FPs. In [36], Ψ_0 is sought in the coordinate representation (5) with regard for two first terms with the functions u_2 and u_3 which are chosen in a definite form with several FPs. In CBF models, the four-particle and higher corrections in the expansion of $E(k)$ were not considered, though taking the subsequent corrections into account changes considerably the curve $E(k)$ [35].

The HNC models are developed in [37, 38] and [39, 40]. In [37, 38], the WF Ψ_0 is sought in the form similar to (6), and the functions a_l are determined from the chain of equations obtained by means of variation of the total energy. The SQ is calculated by the Brillouin–Wigner theory of perturbations. The analysis can be performed without FPs: on the basis of the experimental curve $S(k)$ or the potential (then $S(k)$ is deduced). In [39, 40], Ψ_0 is determined in a similar way, but in representation (5) and with the use of a potential. There, the WF $\psi_{\mathbf{k}}$ and the SQ are calculated within a special method, which is equivalent to the calculation of $\psi_{\mathbf{k}}$ (7). In HNC models, the quantities $E(k)$, E_0 , $S(k)$, and the value of condensate can be calculated quite satisfactorily. As drawbacks, I indicate that the HNC method itself contains certain approximations, and only two first terms are considered in series (5)–(7).

Of interest is the SWF method, whose idea consists approximately in the account of the delocalization of atoms by the introduction of special simple “shadow” factors in the structure of Ψ_0 and $\Psi_{\mathbf{k}}$ in order to partially take higher many-particle corrections into account. The quantity $\Psi_{\mathbf{k}}$ is sought in the form [43, 44]

$$\Psi_{\mathbf{k}} = \int d\mathbf{s}_1 \dots d\mathbf{s}_N \cdot \tilde{\sigma}_{\mathbf{q}} \cdot \exp \left[-C \sum_j |\mathbf{r}_j - \mathbf{s}_j|^2 - \sum_{j < l} (u_r(r_{jl}) + u_s(s_{jl})) \right], \quad (8)$$

$$\tilde{\sigma}_{\mathbf{q}} = \sum_j \exp [i\mathbf{q}\mathbf{s}_j + i\mathbf{q}A(q) \sum_{l(\neq j)} (\mathbf{s}_j - \mathbf{s}_l) \lambda(s_{jl})], \quad (9)$$

where $\mathbf{s}_j$ — shadow coordinates, $u_r(r) = (b/r)^m$ — the McMillan function, $u_s(r) = V_{Aziz}(d_1 \cdot r)/d_2$ — the renormalized Aziz potential, and C, m, b, d_1 , and d_2 — free parameters. The function $\lambda(s_{jl})$ contains still two FPs; whereas $A(q)$ and, in fact, u_s and u_r — free functions. The quantity Ψ_0 is also described by formula (8) with $\tilde{\sigma}_{\mathbf{q}} = 1$. The structure (8), (9) was not strictly deduced, but it is substantiated by a number of arguments with the use of the analogy with the formalism of path integrals. At certain values of FPs, it is possible to well reproduce the experimental data on $E(k)$, E_0 , $S(k)$, and the value of a condensate. A part of FPs is determined under the modeling of Ψ_0 , and the rest of FPs — in the calculation of $\Psi_{\mathbf{k}}$. Note that with $\tilde{\sigma}_{\mathbf{q}} = \sum_j \exp(i\mathbf{q}\mathbf{s}_j)$, i.e., without use of FPs in the derivation of $\Psi_{\mathbf{k}}$, the SQ is reproduced satisfactorily. In [43], $\tilde{\sigma}_{\mathbf{q}}$ was replaced by $\tilde{\sigma}_{\mathbf{q}-\mathbf{q}'}\tilde{\sigma}_{\mathbf{q}'}$, which improves the agreement for $E(k)$. It is probable that the result will be more exact, if $\tilde{\sigma}_{\mathbf{q}}$ will be represented by a series of the form (7) with $\sigma_{\mathbf{q}} = \sum_j \exp(i\mathbf{q}\mathbf{s}_j)$ instead of $\rho_{\mathbf{k}}$. In our opinion, the SWF method in such a form does not allow one to significantly improve the microtheory of He-II, since structure (8), (9) involves only partially higher correlations (as the first iteration [41] of the Schrödinger equation written in the form of a continual integral), whereas the complete consideration requires to deal with infinite series. In addition, the coefficients in (8) are not obtained, so that one has to use many free parameters and functions. This results in the obscurity whether the agreement with experiment is improved due to a more exact description of the microstructure of helium or simply due to a successful selection of a number of FPs.

Thus, all models take only two- and three-particle corrections into account, by neglecting many-particle ones. In this aspect, the models are equivalent. The CV method seems to me the most transparent — it allows one to obtain the equations for the coefficient functions a_l and b_l , the required quantities $E(k)$, E_0 , $S(k)$, and the values of condensates exactly and in a comparatively simple way.

As an efficient numerical tool for the description of the microstructure of He-II, I mention the Monte-Carlo method (MC), in which the problem of next corrections does not arise, since the full solution of the Schrödinger equation is determined numerically at once, though only for the ground state Ψ_0 [48]–[52]. The MC method gives the most exact description of the ground state, its energy E_0 , the structure factor $S(k)$, and the values of all condensates. But the method is not also perfect. In particular, it involves a potential $V(r)$ which is not known exactly for small r . True, at a high barrier $V_0 \equiv V(r \rightarrow 0)$, all potentials are close to the potential of a hard ball; therefore, the results of calculations for different (but high) barriers depend on the barrier height not so strongly. However, some arbitrariness concerning the potential can be noted: e.g., the Aziz potentials include several FPs, and one usually *selects* that Aziz potential among several ones which gives the better agreement of theory with experiment. Another drawback of the method consists in that it is numerical and does not allow one to see the analytic structure of a solution and its details. This yields the third drawback: due to the error of calculations, the method does not allow one to distinguish two cases where the value of a three-particle (for example) condensate is exactly zero or slightly different from zero, say, it equals 0.01. From the physical viewpoint, these cases are basically different. Moreover, the method does not yield the curve $E(k)$ (and all characteristics of helium for $T > 0$), because the Schrödinger equation involves only the energy E , rather than the momentum k . Therefore, by minimizing E , one determines only E for $k = 0$. The whole curve $E(k)$ must be sought involving the other methods, by choosing, for example, $\psi_{\mathbf{k}}$ in the form (7) with variational parameters.

The literature contains the discussions about the nature of a roton [46, 19, 7, 43]. A roton is described by WF (7) which is the exact solution of the N -particle Schrödinger equation; the same function (7) but with small k describes long-wave phonons. This implies that a

roton is a phonon, but with short wavelength. To be more exact, a roton is a wave packet — a superposition of infinite in space waves (7) with various k in the interval Δk . This wave packet is compact, with a size of $\Delta r \sim 10 \text{ \AA}$ [47], which yields $\Delta k \simeq 1/\Delta r \sim 0.1 \text{ \AA}^{-1}$. That is, a roton is a collective excitation, rather than a one-particle excitation or a vortex ring.

In many works, the potential $V(r)$ of the pairwise interaction of He^4 atoms is considered reliably determined. At large distances, $r \gtrsim 2.6 \text{ \AA}$ [53], the potential is small ($|V| \lesssim 10 K$), negative, and well-known. But, at small r , the potential is positive, very large ($V_0 \sim 10^2 \div 10^6 K$), and unknown exactly. Indeed, the electron shells of atoms overlap at small r , the interaction of electrons and the nuclei of both atoms is strong and is modeled [54] in the self-consistent field approximation, which gives only an approximate estimate of the potential (with $V_0 \sim 10^6 K$), rather than the exact potential. The barrier $V_0 \sim 10^6 K$ is also calculated [55] by approximating the potential $V(r \gtrsim 2 \text{ \AA})$ to the region of small r with the use of the quasiclassical approximation, whose exactness is insufficient for the given problem. In view of the approximate nature of the construction of the potential at small r , it is surprising that many works consider the potential at small r to be reliably established and to equal the Aziz potential [53].

On the convergence of QM-methods. In series (5)–(7), the corrections $\sim N$, and there is no small parameter in the equations for a_l and b_l . Nevertheless, the solutions for $E(k)$, E_0 , $S(k)$ and the values of condensates should converge to the exact solution with regard for the increasingly greater number of correlative corrections in (5)–(7). In the chain of linked equations for the functions a_l [30], each of the equations couples the functions a_{l-1} , a_l , and a_{l+1} (and also nonlinear “lower” corrections). Despite the absence of a small parameter in the problem, the solution for the first functions (a_2 , a_3) should converge to the exact one if the increasingly greater number of equations in the chain is solved. This convergence is related not to a small parameter, but to the consideration of higher many-particle correlations.

What does the theory allow one to calculate? In the frame of QM-methods, the SQ can be reliably calculated with regard for only two- and three-particle correlations in (5)–(7) and without use of FPs [8, 33]–[35, 38]. The deviation from experimental data $\sim 10\%$. The quantity E_0 and the value of a one-particle condensate n_1 are determined with significantly less accuracy, for which the experiment gives $E_0 = -7.16 K$, $n_1 \approx 0.05 \div 0.1$. These values can be calculated better within the MC method. For the condensates, the problem consists in that values of the one- and two-particle condensates at $T = 0$ are calculated [31, 32, 56] as the exponent of a sum containing all a_l . Since the corresponding corrections are not small ($\sim 1/2$), taking the following a_l into account changes significantly the value of a condensate: on the transition from the two- to three-particle correlations, this value varies by several times [32, 56]. Thus, if one does not use FPs, then the value of a condensate in the QM-approaches (except the MC method) is calculated with low degree of accuracy. To the best of my knowledge, the FT-approaches do not contain also a quite correct scheme of calculations of the values of condensates for He-II. The value of a two-particle condensate n_2 was calculated only in [32, 56, 57], and no reliable experiment for the determination of n_2 has been proposed till now. The structure factor $S(k)$ is determined from the interaction potential, and all methods give a good agreement with experimental data. As for the potential, the situation looks more complicated. In the region of the potential well, $r \gtrsim 2.6 \text{ \AA}$, the models agree with one another, and the potential is satisfactorily reconstructed from the structure factor [8]. But the height of the potential barrier V_0 is described by different models differently: from $\sim 100 \div 1000 K$ [21, 23, 58, 8, 45] to $\sim 10^6 K$ (with the Aziz potential [53]); in the frame of the MC and SWF methods, such a potential leads to a good agreement of theory and experiment for E_0 , $S(k)$ and the value of a condensate n_1 . The great difference of V_0 , by 3-4 orders, can be related to the efficiency of the potential at small r , the neglect of many-particle corrections in some models [21, 23, 58, 8, 45] (which can cause the underestimation of the

potential by 1-2 orders), or the fact that the Aziz potential is overestimated by 1-2 orders due to approximations made in its derivation.

Let us **summarize**. The general problem concerning all QM-methods consists in that the exact solution is represented by the infinite series (5)–(7), for which all terms cannot be calculated. There are several ways to solve the problem: 1) To realize the break-down in the microtheory, by developing a basically new method of solution or the new form of a solution. For example, it is desirable “to convolve” series (5)–(7) to simpler functions which would be exactly determined. But such a method is not discovered else. 2) To gradually calculate more and more corrections in (5)–(7) without FPs or using them only for the potential to a minimal extent. The convergence of $E(k)$, E_0 , $S(k)$ and the values of condensates can be clearly manifested already after the consideration of, say, 8-particle corrections. 3) However, a system of equations involving all corrections up to the 8-particle one is awkward and complicated. At present, in order to treat only the 5-particle correction, it is necessary to increase the operating rate and the random-access memory of modern personal computers by 3 orders [45]. It seems that such great efforts are not expedient. Indeed, the studied two- and three-particle approximations give a satisfactory agreement between theory and experiment, and it is clear that an increase in the number of considered corrections will improve the agreement.

Sometimes, the authors improve the agreement with experiment with the help of several FPs. Of course, using three and more fitting parameters, it is possible to “explain” any simple curve such as, e.g., the spectrum of quasiparticles of He-II. However, many-particle corrections in (5)–(7) are not small and, hence, are of importance for the solution. If they will be simply neglected, and the curve $E(k)$ will “be constructed” with the help of several FPs, we will face with a successful fitting, rather than with a description of the real microstructure of He-II. In my opinion, to use more than one FP in a model is not expedient.

The FT-methods [16, 20]–[23], as far as I know, meet the same difficulty concerning He-II — the input exact equations following from the first principles cannot be solved exactly, and one is forced to omit many-particle corrections and to solve “truncated” equations. In this case, one fails to correctly introduce a small parameter in the problem (mainly due to the strong interaction of atoms), so that the neglected many-particle corrections are not small, generally speaking.

I mention also the idea of He-II as a quantum crystal [59, 60]. The authors [60] consider that such disordered system as a fluid cannot satisfy the requirement for a system to be completely ordered at $T \rightarrow 0$ (the third principle of thermodynamics). In my opinion, helium has no crystalline lattice. Otherwise, the SQ would be strongly anisotropic like that for the well-known crystalline phases of helium [61]. In addition, the superfluidity was observed in films of helium with thicknesses down to 0.1 [62] and 0.01 [63] of the atomic layer at various mean distances between atoms, whereas this distance for a crystal must be of a single value equal to the lattice constant.

4 Some unsolved problems

At the present time, the structure of the composite condensate of helium is not quite clear in that how many atoms are in the one-, two-particle, and higher s -particle condensates ($s \geq 3$) and why the structure is just such. It is shown in work [32] in the three-particle approximation that the values of three-particle and higher condensates *equal zero* in the ground state of He-II. I note that the three-particle correlations were considered, so that it could be expected that the value of the three-particle condensate is nonzero. I presuppose that the values of three-particle and higher condensates turn out equal zero with regard for all corrections (i.e., for the exact solution) at any temperature. It is possible that the absence of the higher

condensates is related, in a way, to the fact that the function a_l (and b_l) from (6), (7) in each equation of the chain [30] is coupled only with two “adjacent” a_l . This pair originates from the pairwise potential.

Above, quasiparticles meant phonons (including rotons). However, in addition to phonons, helium should contain also microscopic vortex rings, as a heat excitations, with the radius $r \gtrsim 3 \text{ \AA}$, which was noted by L. Onsager [46] long ago. Such rings were registered in experiments with ions [47, 64, 65]. The microscopic description of rings including the construction of the full N -particle WF of a ring was not proposed till now. Only a solution in the mean-field approximation is available [66]. In this case, the N -particle WF of helium with a single ring is sought as the product $\prod_{j=1}^N \Psi(\mathbf{r}_j, t)$ of N identical functions $\Psi(\mathbf{r}, t)$ satisfying the Gross–Pitaevskii equation [67]. The exact parameters of the least ring (its radius, energy, and momentum) are unknown. Respectively, the contributions of rings to the heat capacity of He-II and to the λ -transition are unknown as well. The difference of the experimental heat capacity of helium and that of the ensemble of phonons indicates [68] that the contribution of rings to the heat capacity at temperatures $T = 0.8 \div 1.2 \text{ K}$ does not exceed 6 %. However, it can be significantly greater near T_λ . It is possible also that the rings appreciably affect the value of T_λ . If this is true, one should observe an anomaly on the curve T_λ as a function of the thickness d of a thin film of helium at $d \sim d_c \sim 6 \text{ \AA}$ [69] (d_c — the diameter of the least ring), which can be verified in experiments.

The nature of the λ -transition is not quite clear as well. A number of models were proposed, and some of them well describe the critical indices. But those models are different from the physical viewpoint. In particular, some authors believed that the rings play an important role in the λ -transition (see references in [69]), but the other ones hold the opposite opinion. The question about the nature of the λ -transition is fundamental, because it concerns, in fact, the nature of superfluidity. It is considered to be well established that the superfluidity is related to 1) all motions in He-II are collective, and 2) the spectrum of quasiparticles satisfies the Landau criterion. However, the superfluidity is already absent at a temperature somewhat greater than T_λ . So that, we must answer the questions: What was changed in the medium on the microlevel, and why was the superfluidity broken? This is not quite clear. The process running at T_λ is named sometimes the appearance of microturbulence. From the mathematical viewpoint, this means apparently that 1) structure (2) stops to be a solution of the N -particle Schrödinger equation and 2) a long-range order (LRO) in the medium disappears. The LRO is determined for the s -particle density matrix F_s of He-II as

$$\lim_{|\mathbf{r}_i - \mathbf{r}'_j| \rightarrow \infty} F_s(\mathbf{r}_1, \dots, \mathbf{r}_s | \mathbf{r}'_1, \dots, \mathbf{r}'_s) |_B = \tilde{F}_s(\mathbf{r}_1, \dots, \mathbf{r}_s) \tilde{F}_s^*(\mathbf{r}'_1, \dots, \mathbf{r}'_s), \quad (10)$$

$$\lim_{|\mathbf{r}_i - \mathbf{r}_j| \rightarrow \infty} |\tilde{F}_s(\mathbf{r}_1, \dots, \mathbf{r}_s)|^2 = F_s(\infty) = [F_1(\infty)]^s = \text{const} > 0$$

(in the 3D case), where $i, j = 1, \dots, s$, and condition B means that $|\mathbf{r}_i - \mathbf{r}_j|$ and $|\mathbf{r}'_i - \mathbf{r}'_j|$ are fixed. In a three-dimensional space, just the presence of the LRO causes the appearance of all condensates [31, 32, 56]. However, the things are not so simple with a LRO. Known are the theorems which forbid the existence of LRO in the 2D space in an infinite system. However, all systems in the nature are finite in all directions, and the values of a condensates and the form of LRO for such systems are unknown at present.

This problem was considered for periodic boundary conditions (BCs) [70, 71] which are used explicitly or implicitly in all microscopic models of He-II. But since the periodic BCs are not realized, obviously, in practice for systems consisting of a great number of particles, the problem could be solved more exactly for zero BCs. In this case, the minimal momentum of a particle is not zero, but it is equal to $2\pi/L_j$ (L_j — sizes of the system, L_x, L_y, L_z), which follows also from the uncertainty relations. The condensate is a fine effect, and we may

expect that the proper setting of BCs is important for its evaluation. Apparently, both one- and two-particle condensates exist in finite systems, including finite 2D systems, and “are dispersed” over a number of the lowest levels. In the 3D space, the summation over all levels will result, apparently, in the condensate value $N_{\mathbf{k}=0}$ for an infinite system.

In 2D films, the superfluidity is conserved [62, 63]. If the condensates and LRO exist in such films, like the 3D case, we may conclude that both the condensate and long-range order are the microscopic peculiarities integral to the property of superfluidity. For bounded systems, the criterion for LRO (10) must contain $|\mathbf{x}_i - \mathbf{x}_j| \rightarrow L_{x,0} < L_x$ instead of $|\mathbf{r}_i - \mathbf{r}_j| \rightarrow \infty$, and the analogous substitution will hold for y and z .

It was observed recently that He possesses electric properties [72]–[74], including those without external electromagnetic fields [72, 73]. For the time being, these interesting experiments have no explanation. The electric signals [72, 73] are likely related to the “spontaneous” polarization of helium which appears under certain conditions without external electromagnetic fields, as a result of the mutual polarization of helium atoms [75, 76].

5 Conclusion

I have tried to describe the state of the theory of superfluid He-II. As seen, the theory is gradually developed, but many point remain obscure, including the basic properties of the system and the very property of superfluidity. This presents a wide field for the future studies and, of course, surprises.

The work is performed under the financial support of the Division of Physics and Astronomy of the NAS of Ukraine in the frame of a Target program of fundamental studies N 0107U000396.
